INTRODUCTION

Cirsoid aneurysms (arteriovenous fistulas) of the scalp are rare lesions. These lesions can present as an innocuous looking subcutaneous scalp lump or a large, grotesque, pulsatile mass with a propensity to massive hemorrhage. The superficial temporal artery is frequently involved in traumatic cirsoid aneurysm due to its long unprotected course. We discuss a case of cirsoid aneurysm managed with limited resources due to financial constraints.

CASE REPORT

This 25 year lady presented with progressively increasing pulsatile swelling over right frontal region. She had three episodes of profuse bleeding from the swelling in last three months. She sustained blunt trauma to the right forehead in her childhood. Her general and systemic examination was unremarkable. There were no focal neurological deficits. Local examination revealed a 8 x 8 cm soft, compressible, pulsatile swelling with prominent, dilated and tortuous vessels. Skin over it was healthy except unhealthy scab in the centre. No bony defect was palpable. There was prominent, tortuous and pulsatile right superficial temporal artery with dilated frontal veins. Ultrasound color doppler showed dilated tortuous vessels in the right fronto-temporal region with arterialization of the veins. There was increased blood flow in the right superficial temporal artery. There was also evidence of increased blood flow in the diploic veins suggestive of local trans-cranial drainage (Figure 1). All these finding were suggestive of cirsoid aneurysm fed by right superficial temporal artery. At our institution there are no facilities for angiogram and patient was not affordable to go to any other place. Patient also developed sudden bleeding from the lesion. She was planned for emergency surgical excision of the lesion. Bicoronal scalp flap was planned based on the principles described (to avoid flap necrosis and for adequate exposure) in the literature and the feeding anterior branch of right superficial artery was cut between ligatures. The scalp flap was raised along with the pericranium. The bleeding from the bone is controlled with bone wax and monopolar diathermy. Other feeding arteries were identified along their course at the base of the scalp flap, and the vessels traced distally towards the nidus of the scalp malformations and ligated. The pericranium and the galea are circumferentially incised and the vascular malformation was excised. On follow up patient was doing well and color Doppler showed total excision of the lesion (Figure 1).
DISCUSSION

The etiology of cirsoid aneurysms is still controversial. However, it is generally accepted that it may be either of congenital or traumatic origin. About 10 to 20% of scalp arteriovenous malformations develop following penetrating or non-penetrating trauma to the scalp. Most of the patients reported in the literature had a history of progressive increase in the size of the lesion and had become symptomatic in the third decade of life. The clinical manifestations relate primarily to the size of the fistula, and patients may present with loud bruit, hemorrhage, and throbbing headache and in severe cases, scalp necrosis. Hemorrhage from these lesions is uncommon and usually associated with large vascular malformation. Angiography is the gold standard investigation to delineate the lesion and to exclude an intracranial component. Other supplementary investigations are CT, MRI, MRA, angiography and color doppler studies. In treating these types of AVM, surgical excision has been the most common method of obliteration. These procedures are necessarily extensive, and, for a complete cure, the entire fistula had to be removed; otherwise, an AVM will likely recur, together with recruitment of a collateral blood supply. Other treatment modalities in cases of a cirsoid aneurysm or AVM of the scalp or face, direct-puncture embolization with NBCA, absolute alcohol, or a metallic thrombogenic coil with good results has been reported.

CONCLUSION

Diagnosis of cirsoid aneurysm of the scalp can be made easily on clinical grounds and a complete angiographic study of the lesion is the gold standard. However when the facilities and affordability are limiting factors and patient needs emergency care as in the present case optimum use of available resources, supported by the literature can result in good outcome.
